Efficient mucosal vaccination mediated by the neonatal Fc receptor

Lilin Ye\(^1\), Rongyu Zeng\(^1\), Yu Bai\(^1\), Derry C Roopenian\(^2\) & Xiaoping Zhu\(^1,3\)

Almost all infectious diseases are initiated at mucosal surfaces, yet intramuscular or subcutaneous vaccination usually provides only minimal protection at sites of infection owing to suboptimal activation of the mucosal immune system. The neonatal Fc receptor (FcRn) mediates the transport of IgG across polarized epithelial cells lining mucosal surfaces. We mimicked this process by fusing a model antigen, herpes simplex virus type-2 (HSV-2) glycoprotein gD, to an IgG Fc fragment. Intranasal immunization, together with the adjuvant CpG, completely protected wild-type, but not FcRn knockout, mice after intravaginal challenge with virulent HSV-2 186. This immunization strategy induced efficient mucosal and systemic antibody, B- and T-cell immune responses, with stable protection for at least 6 months after vaccination in most of the immunized animals. The FcRn-IgG transcellular transport pathway may provide a general delivery route for subunit vaccines against many mucosal pathogens.

Vaccines that protect against infectious agents entering the body at mucosal surfaces must induce both mucosal and systemic immune responses to cope with early infection and pathogen spread\(^1\)–\(^4\). The close association between mucosal epithelial cells and the immune effector cells within the lamina propria\(^1\)–\(^3\) suggests that delivery of immunogens through the mucosal surface would be an ideal approach to achieve mucosal and, potentially, systemic immunity. However, the intercellular tight junctions of epithelial monolayers lining the mucosal surfaces render them impervious to macromolecule diffusion\(^5\). One approach to circumvent this problem involves targeting mucosal vaccines onto differentiated microfold (sometimes called ‘M’) cells that punctuate the mucosal epithelium\(^6\). However, because columnar epithelial cells make up the great majority of mucosal surfaces, alternative mucosal vaccine delivery strategies that target these abundant epithelial cells may increase the efficacy of mucosal vaccines.

FcRn allows fetuses or newborns to obtain maternal IgG through the placental or intestinal route\(^7,8\). However, the receptor can also transport IgG antibody across mucosal surfaces in adult life\(^9\)–\(^12\) and confer resistance to intestinal pathogens\(^12\). The observation that FcRn can transport IgG across mucosal epithelia suggested to us that fusion of an antigen to IgG Fc may enable FcRn-mediated transport of the antigen across the mucosal barrier. To test this possibility, we worked with the model pathogen HSV-2, which initiates infection primarily at the mucosa of the genital tract\(^4\). The model antigen, HSV-2 gD, is important in early viral infection and a target for both humoral and cellular immunity. We determined the ability of FcRn to deliver a fusion of gD to the Fc fragment across the respiratory mucosal barrier and then further defined the protective immune responses and mechanisms relevant to this mode of mucosal vaccine delivery.

To target gD for FcRn-mediated uptake, we first generated the fusion protein, gD-Fc/wt, by cloning the extracellular domain of HSV-2 gD in frame with a modified form of the mouse IgG2a Fc fragment (Supplementary Fig. 1). We also generated a similarly modified gD-Fc/mut fusion protein, which cannot bind FcRn owing to H→A substitutions at positions 310 and 433 (ref. 13). In both cases, the complement C1q-binding motif was eliminated to abrogate C1q binding\(^14\) (Supplementary Fig. 1a). To ascertain whether the gD-Fc/wt, but not the gD-Fc/mut, fusion proteins were transported by FcRn, we assayed for FcRn-dependent transcytosis of intact gD-Fc/wt in inner medullary collecting duct cells expressing FcRn\(^15\) (Supplementary Fig. 2a). We then determined whether the gD-Fc/wt reached the bloodstream after intranasal inoculation. We confirmed FcRn expression in mouse trachea and lung and its absence in the adult intestine (Supplementary Fig. 2b). After intranasal (i.n.) administration of 20 µg of either gD, gD-Fc/mut or gD-Fc/wt protein in FcRn WT and FcRn knockout mice\(^16\), we noted substantial gD-Fc/wt accumulation in the sera of FcRn WT mice only (Supplementary Fig. 2c). These results showed that efficient delivery of gD across the respiratory barrier to the bloodstream was dependent on the Fc moiety and its ability to interact with FcRn.

Engagement of FcRn greatly increased the efficiency by which gD antigens induced antigen-specific antibody and cellular immune responses. We then determined whether FcRn-dependent transport augmented the potential of the gD protein to mount an immune response. Mice were immunized i.n. with gD-Fc, gD protein or PBS, all in combination with CpG, and received boosters after 2 weeks. The free gD protein, not linked to an Fc fragment, allowed us to both evaluate FcRn-independent effects in vivo and determine the magnitude of any observed enhancement in immune responses conferred by fusion to Fc and recognition by FcRn. Because at least some immature dendritic cells are immunologically tolerant in vivo, we co-administered CpG, a ligand for Toll-like receptor 9, in an effort to overcome possible mucosal tolerance\(^17\). In a different study, we found that co-administration of CpG oligonucleotides with an Fc fusion

protein was required to induce a robust IgG response (unpublished data). Significantly (P < 0.01) higher titers of IgG were seen in the gD-Fc/wt-immunized mice when compared with the gD-, gD-Fc/mut-, gD-Fc/wt/KO-immunized and PBS-treated groups (Fig. 1a). Moreover, sera from the gD-Fc/wt-immunized mice exhibited strong neutralizing activity (Fig. 1b) and after passive transfer, protected animals from intravaginal challenge more efficiently than sera from all other groups (Supplementary Fig. 3). Likewise, mice immunized with gD-Fc/wt had a significantly higher frequency (P < 0.01) of IFN-γ-producing CD4+ and CD8+ splenic T cells in response to gD stimulation, relative to the other groups (Fig. 1c). The cytokine responses were dominated by IFN-γ and interleukin (IL)-2; there was little IL-4 production (Fig. 1d). The existence of this dominant T-helper-1 cell cytokine response was also supported by a major IgG2a subclass in the sera of the immunized mice (Supplementary Fig. 4). It remains uncertain whether this polarized T-cell response was caused by mucosal immunization by means of FcRn targeting or, more likely, by the Cpg used as adjuvant.17

That FcRn-targeted mucosal delivery of subunit vaccine elicited a strong mucosal immune response is supported by four lines of evidence. First, to ascertain the ability of the FcRn-targeted vaccine to induce local luminal immune responses, we monitored the activated germinal center reaction in the mediastinal lymph nodes (MeLNs) and spleens 10 d after the boost, as the nasopharynx-associated lymphoid tissue and MeLNs that drain the lungs are where mucosal immune responses are initiated against i.n. administered antigens18,19. Activated germinal centers are characterized by the presence of peanut agglutinin (PNA)-positive areas and high-level expression of FAS apoptotic death receptor in activated B cells (B220+)19. The gD-Fc/wt immunization induced a substantially higher percentage of FAS+ PNA+ B220+ B cells in the MeLN or spleen in comparison with that of other groups (Fig. 2a), which was further validated by immunofluorescence imaging (Fig. 2b). In addition, the germinal center structure in the MeLNs in WT mice immunized by gD-Fc/wt was sustained much longer in comparison with that of other groups (Fig. 2c). Administration of Cpg alone failed to elicit appreciable formation of germinal centers in the draining MeLNs, spleens or lungs (Supplementary Fig. 5). Because the formation and maintenance of germinal centers generally lead to the differentiation of memory B cells and long-lived plasma cells, we also examined the mesenteric, cervical and inguinal lymph nodes. We did not detect germinal center formation or a significant number of IFN-γ-secreting T cells at those sites.

Second, it has been shown that i.n. administered antigens can induce bronchus-associated lymphoid tissue (iBALT) in the lung, which is similar to germinal center structures.19 Such germinal center–like structures could be detected in the lungs of gD-Fc/wt–, but not gD-Fc/mut-immunized mice or other groups of immunized animals (Fig. 2d and Supplementary Fig. 5). The germinal center–like iBALT in the lung was most likely induced locally because of the presence of the transported gD antigen in the MeLNs and lung.

Third, to assess the ability of FcRn–targeted mucosal immunization to induce gD-specific antibody in mucosal secretions, we collected bronchial alveolar lavage (BAL) and vaginal washings 10 d after the boost and analyzed both for gD-specific IgG and IgA by enzyme-linked immunosorbent assay (ELISA). Significantly (P < 0.01) increased levels of gD-specific IgG were present in the BAL and vaginal washings (Supplementary Fig. 6) of the gD-Fc/wt-immunized mice. WT, but not FcRn knockout, mice that received gD-Fc/wt had high levels of gD-specific IgG in BAL and vaginal washings (P < 0.01; Supplementary Fig. 6), suggesting that the induction of mucosal IgG is mediated by FcRn. IgG levels in BAL and vaginal washings were much higher than levels of IgA (Supplementary Fig. 6).

Fourth, with respect to T-cell immune responses in the lung and MeLNs, 4 d after the boost we detected significantly (P < 0.01) more IFN-γ-producing CD4+ and CD8+ T cells (Fig. 2e,f) in response to gD stimulation in mice immunized with the gD-Fc/wt. We conclude that the combination of Cpg with antigen targeting to
FcRn produced strong antibody as well as T-cell mucosal immune responses. An efficient protective vaccine must induce immunity in the mucosa to block viral entry. FcRn-targeted mucosal immunization may provide an efficient approach for the development of such protective mucosal vaccines.

In addition to humoral and cell-mediated immunity at the mucosal delivery site, an effective mucosal subunit vaccine should also elicit immunity in systemic compartments that can access mucosal tissues distant from the immunization site. Studies have found that mucosal immunization using the intranasal route is effective for generating antibody and T-cell immune responses in the female

Figure 2 Local immune responses induced by FcRn-targeted mucosal immunization. (a) Accumulation of activated B cells in germinal centers in the mediastinal lymph nodes (MeLN) and spleen. Representative flow cytometric analyses of germinal center B cells among CD19+ B220+ B cells in the MeLNs and spleen 10 d after the boost. B220+ PNA<sup>high</sup> cells are B cells that exhibit the phenotypic attributes of germinal center B cells. The germinal center staining in spleen was used as a positive control. Numbers are the percentage of activated germinal center B cells (PNA<sup>+</sup> FAS+) among gated B cells and are representative of three independent experiments. (b) Germinal center formation and presence of activated B cells following immunizations as indicated. Frozen MeLN sections at day 10 from the immunized mice were co-stained with biotin-PNA (developed with avidin-FITC) and Alexa647 labeled anti-IgD. Scale bars represent 50 µm. (c) Quantitative analysis of germinal centers following immunization. The dynamics of the frequency of germinal center B cells (FAS<sup>+</sup> PNA<sup>+</sup>, gated on CD19<sup>+</sup> B220<sup>+</sup> cells) were plotted on days 10, 22 and 35 after the boost. Data indicate the mean and S.E.M., n = 5 mice. (d) The formation of inducible bronchus-associated lymphoid tissue (iBALT). Frozen serial sections of the lung were stained with biotin-PNA (germinal center, red) and anti-B220 (B cells, green), followed by Alexa 488-conjugated IgG of corresponding species and Alexa 555-Avidin. The nucleus is stained with DAPI (blue). A germinal center-like structure is shown in the merged panel by the white color. The data are representative of at least three independent mice. Images were originally obtained at 10x magnification. Scale bars, 100 µm. (e,f) Presence of HSV-2 gD-specific T lymphocytes in the lung (e) and MeLNs (f). Lung or MeLN cells were collected from mice 4 d after the boost. Lymphocytes were gated based on their forward scatter (FSC) versus side scatter (SSC) profile. Intracellular staining for IFN-γ was performed after surface staining of CD4 and CD8 molecules. The profiles shown are representative of five mice from three separate experiments. Numbers indicate percentages of IFN-γ-producing T lymphocytes from gated CD4<sup>+</sup> and CD8<sup>+</sup> T cells.

Figure 3 FcRn-targeted mucosal immunization provides protective immunity to intravaginal challenge with virulent HSV-2 186. (a) Mean survival following genital HSV-2 challenge. Four weeks after the immunization, groups of five mice were challenged intravaginally with 1 × 10<sup>5</sup> p.f.u. of HSV-2 strain 186. Percentage survival on the indicated days is calculated as the number of mice surviving divided by the number of mice in each group and represented three similar experiments. (b) Mean of viral titers following HSV-2 challenge. Virus titers were measured from vaginal washes by taking swabs on the indicated days after HSV-2 inoculation based on a plaque assay on Vero cell monolayers. (c) Increased presence of HSV-specific T lymphocytes in the vaginal epithelium after challenge. Lymphocytes were harvested from collagenase-digested vaginal tissues 4 d after intravaginal inoculation with virus. Intracellular staining for IFN-γ expression on CD4<sup>+</sup> and CD8<sup>+</sup> T cells was analyzed after gating on viable CD3<sup>+</sup> lymphocytes. The numbers in each column show the percentage of IFN-γ-positive T lymphocytes from the gated CD4<sup>+</sup> or CD8<sup>+</sup> T cells. Data shown are representative of three experiments, using three mice per experiment.
Figure 4. Increased memory immune response in FcRn-targeted mucosal immunization. (a) Induction of gD-specific memory B cells in the spleen. The frequency of gD-specific memory B cells was assessed 6 months after the boost. Memory B cells, defined as B220⁺ gD-surface*, were analyzed 6 months after the boost by FACS. Purified gD proteins were labeled with Alexa Fluoro647. Spleen cells (2 x 10⁶) were incubated with the 1 µg Alexa Fluoro647-labeled gD proteins and B220 antibody. Numbers in the quadrants are the percentage of gD-specific memory B lymphocytes. (b) Long-lived HSV gD-specific antibody-secreting cells in the bone marrow. Bone marrow cells (BMC) removed 6 months after the boost were plated on gD-coated plates and quantified by ELISPOT analysis of IgG-secreting plasma cells. Data were pooled from two separate experiments with five mice in each experiment. The graphs were plotted based on the average ELISPOT for replicate wells. Values marked with asterisks are significantly greater (P < 0.01) from the gD-Fc/wt protein-immunized mice than those of other groups as indicated. (c) Durability of HSV-2 gD-specific serum IgG response. In two separate experiments, HSV-2 gD-specific IgG was quantified by ELISA in serum by endpoint titer from five mice at 6 months after the boost. HSV-specific IgG antibody was not detected in PBS-immunized mice. (d) Long-lived gD-specific T cell memory to FcRn-targeted mucosal vaccination. Spleen cells were isolated from the immunized mice 6 months after the boost, stained with CFSE and stimulated in vitro with 20 µg/ml of purified gD for 4 d. Data are expressed in CFSE histograms of fluorescence intensity versus the number of fluorescing cells, indicating the percentage of the cell population positive for CD4 and CD8 antigen. Numbers in the quadrants are the percentage of CD4⁺ and CD8⁺ proliferating T cells. Representative flow cytometry profiles of two similar experiments with three mice per group are shown. Immunization conditions are displayed on the top. (e) Mean survival following genital HSV-2 challenge 6 months following the boost. The immunized mice were challenged intravaginally with 1 x 10⁴ p.f.u. of HSV-2. Percentage of mice protected on the indicated days is calculated as the number of mice surviving divided by the number of mice in each group (n = 5). (f) Proposed model of FcRn-mediated mucosal vaccine delivery. The Fc-fused antigens are transported by FcRn and targeted to the mucosal antigen-presenting cells (APC), such as dendritic cells. Antigen is taken up by pinocytosis or FcγR1-mediated endocytosis in APCs, then processed and presented to T cells.

genital tract⁴. Perhaps intranasal immunization stimulates cells in the nasopharynx-associated lymphoid tissue and MeLNs, leading to the migration of antibody-secreting cells and T cells generated in the airway into the genital tract.²⁰ We intravaginally challenged immunized mice with a lethal dose of HSV-2 186 strain 4 weeks after the boost. All FcRn WT mice (n = 15) immunized with gD-Fc/wt survived with no obvious symptoms (Supplementary Fig. 7a), whereas gD-Fc/wt-immunized FcRn knockout mice (n = 15) were incompletely protected (Fig. 3a). These data indicate that full protection is dependent on FcRn. Additionally, virus titers measured in the vaginal washings showed that the gD-Fc/wt-immunized mice had eliminated the virus by day 4 after challenge (Fig. 3b), whereas substantial viral levels remained in the other groups of mice through day 6.

Several immune mechanisms may account for the protection of the distal vaginal mucosa. First, both mucosal and systemic antibody responses may play an important protective role. The sera passively transferred from the gD-Fc-immunized mice conferred a high level of protection (Supplementary Fig. 3) and a considerable amount of gD-specific IgG appeared in the vaginal secretions (Supplementary Fig. 6). After immunization with attenuated HSV-2, IgG contributes the majority of protection in mouse vaginal secretions⁸. Second, the presence of T lymphocytes in the vaginal epithelium of HSV-2–challenged mice coincided with virus clearance. IFN-γ is clearly indispensable for resistance to HSV-2 infections.¹¹ The gD-Fc/wt protein induced a significantly higher frequency of IFN-γ-producing CD4⁺ and CD8⁺ T cells in the vaginal tissues from the challenged mice (Fig. 3c). Overall these results demonstrate that FcRn-targeted mucosal immunization efficiently induced protective immunity.

Our studies further suggested that FcRn-targeted mucosal delivery of vaccine engendered an effective memory immune response. Immunological memory²²,²³ has been a concern in protein-based subunit mucosal vaccine development because although preparations frequently elicit immunity immediately after vaccination, protection decreases rapidly. A striking feature of our study is that FcRn-targeted mucosal immunization promoted and sustained high levels of gD-specific plasma cells and memory B and T cells. First, gD-Fc/wt-immunized mice developed considerably higher numbers of splenic memory B cells responsive to gD stimulation 6 months after the boost (Fig. 4a). Using enzyme-linked immunosorbent spot (ELISPOT), we also found the significantly (P < 0.01) higher number of gD-specific, IgG-secreting plasma cells in the bone marrow of mice immunized with gD-Fc/wt (Fig. 4b and Supplementary Fig. 8). It remains to be determined if gD-specific, IgA-secreting plasma cells also develop.
Second, higher titers of gD-specific IgG were maintained for 6 months after the boost in the mice immunized with the gD-Fc/wt (Fig. 4c). Both the increase in germinal center and memory B cells in the spleen and the existence of long-lived plasma cells in the bone marrow niche can account for the maintenance of high levels of gD-specific IgG in circulation. Third, we detected large numbers of CD4+ (Fig. 4d) and CD8+ (Fig. 4d) memory T-cell proliferation by carboxyfluorescein diacetate succinimidyl ester (CFSE) in response to gD recall in the mice immunized with gD-Fc/wt, but not in any of the other groups. This result was also verified by considerably increased numbers of actively proliferating T cells over time (Supplementary Fig. 9). These data indicate that the gD-specific T cells had maintained proliferative potential at least 6 months after the boost. Although the reason for the high memory T-cell activity is not completely clear, IL-2–producing T cells formed in the responding T-cell population (Supplementary Fig. 10) may be important because IL-2 is important in the successful long-term survival of memory T cells in vivo24. Fourth, to test if the memory immune response provided protection, we again intravaginally challenged the immunized mice with HSV-2 186 strain 6 months after the boost. Mice immunized with the gD-Fc/wt proteins exhibited less severe disease symptoms (Supplementary Fig. 7b) and had 80% survival (Fig. 4e), whereas the majority of mice in other groups succumbed to lethal mucosal infection.

Overall, our study shows that the FcRn/IgG transport pathway can be exploited to greatly enhance the efficacy of mucosally administered vaccines. Previous studies have taken advantage of Fc fusion proteins to augment the T-cell immune response to myelin basic protein25, and mucosally administered inactivated Francisella tularensis live vaccine strain/antibody immune complexes have been shown to enhance protection against a highly virulent strain26. We have shown that FcRn-targeted mucosal immunization differs considerably between WT and FcRn knockout mice or the gD-Fc/wt and the gD-Fc/mut-immunized mice in terms of mucosal and systemic immune responses, cytokine expression profiles, the maintenance of T- and B-cell memory and long-lived bone marrow plasma cells, and resistance to infection. We establish this principle using a modified form of the mouse IgG2a Fc fragment to facilitate the vaccine antigen delivery across the mucosal barrier. Earlier studies have shown intranasal and intravaginal immunization with gD or gB proteins in combination with CpG elicited immune responses and conferred partial protection to subsequent vaginal challenge with HSV-2 (refs. 27–30). The mechanism by which ‘plain’ gD or gB proteins crossed the airway or female genital epithelial barrier in those studies is not clear. The treatment of mice with agents, such as volatile anesthetics halothane and isoflurane or 0.5% Tween27–30, could compromise the integrity of the alveolo-capillary or mucosal epithelial barrier31,32. Moreover, injections with Depo-Provera before vaginal immunization28–30 may affect the integrity of cell junctions between the vaginal epithelial cells4. In agreement with a previous report33, our other studies on examination of the effect of CpG on protein transport across the nasal/tracheal mucosa (unpublished data) are not consistent with an effect of CpG on mucosal permeability or passive transport. Our results document the benefits of FcRn targeting to maximize the potential of mucosally administered vaccines to counteract mucosal pathogens.

We suggest the following model for FcRn-targeted immunization (Fig. 4f). In general, mucosal dendritic cells capture antigens in mucosal-associated lymphoid tissues, and migrate to draining lymph nodes where they can activate T cells34,35 and initiate the cognate B-cell response. Persistence of vaccine antigens can facilitate long-term memory immune responses22,23. Thus, although FcRn-mediated transport is necessary for effective mucosal immunization, the ability of FcRn to protect gD-Fc/wt proteins from degradation may further support the development of systemic immunity by increasing the persistence of gD-Fc/wt in circulation. Furthermore, this same protection property may augment long-term humoral immunity by maintaining high levels of systemic IgG antibodies specific for gD-Fc/wt. It remains to be determined whether this delivery method can augment pre-existing immunity. Our findings suggest that FcRn-targeted mucosal immunization may be an effective strategy for maximizing the efficacy of vaccinations directed against a broad range of mucosal pathogens.

ONLINE METHODS

Cells, antibodies and virus. Inner medullary collecting duct (IMCD) cell line and IMCD cells expressing rat FcRn were obtained from Neil Simister. Vero and Chinese hamster ovary (CHO-K) cells were purchased from American Tissue Culture Collection (ATCC). IMCD, Vero and CHO cells were maintained in DMEM complete medium (Invitrogen Life Technologies) supplemented with 10 mM HEPES, 10% FBS, 2 mM L-glutamine, nonessential amino acids, and penicillin (0.1 µg/ml)/streptomycin (0.292 µg/ml). Recombinant IMCD and CHO cells were grown in 400 µg/ml of G418, when necessary. Cells from spleen or bone marrow were grown in complete RPMI 1640 medium. HSV-2 strain 186 was from Lawrence Stanberry and HSV-2 stocks were prepared by infection of Vero cell monolayers at a multiplicity of infection (MOI) of 0.01. All cells and viruses were grown in a humidified atmosphere of 5% CO2 at 37 °C. Affinity-purified antibody for mouse FcRn was made as previously described30. Horseradish peroxidase (HRP)-conjugated donkey anti-rabbit or rabbit anti-mouse antibodies was purchased from Pierce (Rockland). Purified mouse IgG and chicken IgY was from Rockland Laboratories, and HRP-conjugated goat anti-mouse IgG1, IgG2a and IgG3 were from Southern Biotech. All DNA-modifying enzymes were purchased from New England Biolabs. Purified HSV-2 glycoprotein D was purchased from Meridian Life Science.

Expression of gD-Fc fusion proteins. The cDNA encoding the extracellular domain of HSV-2 gD (26–340 aa) was amplified by PCR from a plasmid provided by Patricia G. Spear using the primer pair (5′-CGGATCCCGAGCCACCTCCTC-3′, 5′-AGATCCCGAGCCACCTCTCTC CGGACCCACCCCGCTATCCGGCGGTTGCTGCGG-3′). The antisense primer introduces an extension with 14 codons for glycine and serine residues (GGSGGGGGGGGGGSGS). The Fc-fragment of mouse IgG2a containing the hinge, an extended CH2 and a CH3 domain was amplified by RT-PCR from the OKT3 hybridoma. The mouse IgG2a Fc fragment was used because mouse IgG2a, but not IgG1, is capable of binding mouse FcRγ, a high-affinity receptor for IgG. Similarly, the forward primer for IgG2a Fc has complementary glycine and serine codons for gD. A mutant Fc (HQ310 and HN433), unable to bind mouse FcRn, was made by oligonucleotide site-directed mutagenesis (Clontech) and designated as an Fc/mut. To construct a nonlytic Fc fragment, oligonucleotide site-directed mutagenesis was used to replace the C1q binding motif Glu318, Lys320, Lys322 with Ala residues14. Fusions were then performed in a PCR-based gene assembly approach by mixing the cDNA for gD and the Fc fragment. All these DNA fragments were ligated into the pCDNA3 vector. Each construct was verified by DNA sequencing.

The plasmids containing the chimeric gD-Fc fragment were transfected into CHO cells. G418-resistant clones were selected for secretion of gD-Fc fusion protein. SDS-PAGE and western blot analysis were performed to assess the recombinant fusion proteins in serum-free medium (Invitrogen). The highest secreting clones were screened. Recombinant proteins were purified from CHO cell supernatants by affinity chromatography using Protein A Sepharose 4 Fast Flow (Amersham) or goat anti-mouse IgG affinity column (Rockland). Protein concentration was measured with Coomassie (Bradford) protein assay kit (Pierce) using mouse IgG2a as standard.

Western blot analysis and SDS-PAGE gel electrophoresis. The proteins or cell lysates were resolved on a 12% SDS-PAGE gel under reducing or non-reducing conditions. Proteins were transferred onto a nitrocellulose membrane (Schleicher & Schuell). The membranes were blocked with 5% nonfat milk, probed separately with anti-gD, anti-IgG Fc antibody or anti-mouse FcRn for 1 h, and followed by incubation with HRP-conjugated rabbit anti-mouse or donkey anti-rabbit antibodies. All blocking, incubation and washing were performed in PBST solution (PBS and 0.05% Tween 20). Proteins were visualized by enhanced chemiluminescence (ECL) (Pierce).

In vitro and in vivo transcytosis. The in vitro IgG transport assay was performed as a modification of previously described methods15,36. IMCD cells expressing rat FcRn were grown on transwell filter inserts (Corning Costar) to form a monolayer exhibiting transepithelial electrical resistances (TER, 300 Ω.cm2). TER was measured using a tissue-resistance measurement equipped with planar electrodes (World Precision Instruments). Monolayers were equilibrated in Hanks’ balanced salt solution. Fusion proteins (50 µg/ml) were applied to the apical compartment, and incubated with DMEM medium supplied with or without 1 mg/ml of mouse IgG or chicken IgY as competitors for 2 h at 37 °C degree. Transported proteins were sampled from the basolateral chamber and analyzed by reducing SDS-PAGE and western blot–ECL. For in vivo transport, the bioinylated 20 µg of fusion proteins or gD alone in 20 µl of PBS were administered i.n. into the mice that were anesthetized with 100 µl of avertin (40 mg/ml). At indicated time points or 8 h later, transported proteins in sera were determined by ELISA.

Mouse immunization and virus challenge. Six- to eight-week-old female inbred C57BL/6 mice were purchased from Charles River. FcRn knockout mice on a C57BL/6 background36 were from the Jackson Laboratory. All mice were housed in the animal resources facility at the University of Maryland. All animal studies were reviewed and approved by the Institutional Animal Care and Use Committee. All proteins and PBS were mixed with immunostimulatory DNA rich in CG motifs CpG oligonucleotide 1826 (abbreviated CpG) to overcome possible mucosal immune tolerance37. Groups of five mice were immunized i.n. with 20 µl of 20 µg gD-Fc/wt, gD-Fc/mut, or recombinant gD alone or in combination with 20 µg Cpg (5′-TCCATGACCTTCCTGACG TT-3′) (Invitrogen) per immunization at weeks 0 and 2 with an intraperitoneal injection of 100 µl of avertin (40 mg/ml). An additional group of five mice was mock-immunized with PBS following the same schedule. Mice were kept on their backs under the influence of anesthesia to allow the inoculum to be taken up.

Mice were inoculated with viruses intravaginally as described previously27,38. Briefly, each mouse was subcutaneously treated with 3 µg of medroxyprogesterone acetate (Depo-Provera) 10 d before virus inoculation. Hormonal pretreatment was necessary to induce susceptibility of mice to genital HSV-2 inoculation, which may cause thinning of the genital epithelium or induction of the HSV entry receptor, nectin-1, on vaginal epithelial cells. Mice anesthetized by avertin (40 mg/ml, Sigma) were infected intravaginally with 1 × 104 plaque-forming unit (p.f.u.) of HSV-2 strain 186. Mice were kept on their backs under the influence of anesthesia for 45 min to allow infection. Mice were monitored for 15 d for disease and death. Mice exhibiting severe disease symptom were euthanized. For virus titration, virus was inoculated into Vero cells and incubated for 45 min at 37 °C. The cells were washed and DMEM containing 0.8% methylcellulose and 2% FBS was added to overlay the cells. The cells were cultured for 3 d, the overlay was removed, and the cells were fixed with 3.7% formaldehyde for 1 h, and stained with 1% crystal violet.

Preparation of single-cell suspensions from lymph nodes, spleen, lung and vaginal tissues. Spleens and lymph nodes39 were made into single-cell suspensions by passage through a sterile mesh screen. Cells were resuspended in Hanks’ balanced salt solution (HBSS) and counted by trypan blue dye exclusion. For each experiment, cells were generally pooled from 3–5 mice in each group. For preparation of single-cell suspensions from the lungs, mice were anesthetized with 400 µl of avertin (40 mg/ml) by intraperitoneal injection. Lungs were perfused with 10 ml PBS through the right ventricle, removed, minced with blades, and incubated with HBBS containing 2.5 mM HEPES and 1.3 mM EDTA at 37 °C for 30 min, followed by treatment at 37 °C for 1 h with 2.5 mg/ml collagenase D (Roche) in RPMI 1640 medium containing 5% FBS. The resulting cells were filtered through a 70-µm filter and used for fluorescence-activated cell sorting (FACS) analysis. For isolation of vaginal cells, the vagina was excised, cut longitudinally and minced with a sterile scalpel in complete RPMI 1640 culture medium. Minced tissues (epithelium and lamina propria) were digested in complete medium with sterile 0.25% collagenase D (Sigma). Digestion was accomplished with shaking incubation at 37 °C for 30 min. After digestion, tissues and cells were filtered through a sterile gauze mesh and washed with RPMI 1640 medium, and additional tissue debris was excluded by slow-speed centrifugation for 1 min. Cells were collected from the supernatant by centrifugation, resuspended in HBSS and counted by trypan blue dye exclusion.

Flow cytometry. Single-cell suspensions from the spleen, lung or vaginal tissues were collected and cells were spun down. Erythrocytes were then lysed in 0.14 M NH4Cl, 0.017 M Tris–HCl at pH 7.2 on ice for 5 min.
Cells were preincubated with an Fc block (monoclonal antibody (mAb) to CD16–CD32, 2.4G2, PharMingen) and washed in FACS buffer (HBSS, 2% BSA, 0.01% sodium azide). Cells were incubated with specific antibody (0.25 µg/10^6 cells/100 µl) directly conjugated to fluorescein isothiocyanate (FITC), phycocerythrin, washed, transferred to FACS buffer and analyzed using a FACS Aire (Becton Dickinson) and FlowJo software (Tree Star). The mAbs (PharMingen) we used were anti-CD3ε, 500A2; anti-CD4, RM4-5; anti-CD8, 53-6.7; anti-IFN-γ, XMG1.2; anti-B220, RA3-6B2; FAS, Jo2; CD19, 1D3. PNA was from Sigma. Purified HSV-2 gD proteins were labeled with Alexa Fluor 647 (PharMingen) we used were anti-CD3ε, 500A2; anti-CD4, RM4-5; anti-CD8, 53-6.7; anti-IFN-γ, XMG1.2; anti-B220, RA3-6B2; FAS, Jo2; CD19, 1D3. PNA was from Sigma. Purified HSV-2 gD proteins were labeled with Alexa Fluor 647 protein labeling kit (Invitrogen) according to the manufacturer’s instructions. Cells incubated with isotype control antibodies were used to determine the background fluorescence. The isotype control antibodies included in each experiment were considered the true baseline fluorescence used to evaluate and illustrate the results for the cell-specific antigen markers.

**T-cell proliferation.** Single-cell suspensions from mouse spleen were suspended in RPMI-1640 with 1% FCS, 2.5 mM HEPES at 10^7/ml. Carboxyfluorescein diacetate succinimidyl ester (CFSE, 5 mM stock, Invitrogen) was diluted or vaginal infiltrating lymphocytes incubated for 4 h with 25 µg/ml gD protein or medium alone. Cells were then cultured for another 6 h in the presence of brefeldin A (Sigma). The cells were washed twice with RPMI-1640 with 10% FCS. Labeled cells (5 × 10^5) were plated into 96-well plates in 200 µl of medium and cultured for 5 d. The cells were then harvested and subjected to flow cytometry assay.

**Intracellular cytokine staining.** Intracellular IFN-γ production by primed CD4+ and CD8+ T cells was evaluated using bulk splenocytes or isolated lung or vaginal infiltrating lymphocytes incubated for 4 h with 25 µg/ml of the purified gD protein or medium alone. Cells were then cultured for another 6 h in the presence of brefeldin A (Sigma). The cells were washed and incubated with anti-CD16/CD32 antibody to block Fcy receptors, and stained with anti-mouse CD4, CD8 and CD3 antibodies for 15 min at 4 °C. After fixation and membrane penetration with Cytofix/Cytoperm Plus (BD Biosciences), cells were stained for intracellular IFN-γ for 30 min on ice. Cells were washed three times, resuspended in FACS buffer and analyzed by flow cytometry.

**ELISA, ELISPOT and neutralization test.** For the detection of gD-specific antibodies in serum, bronchial lavage and vaginal fluid, high-binding ELISA plates (Maxisorp, Nunc) were coated with 5 µg/ml of recombinant gD protein in PBS and incubated overnight at 4 °C. Plates were then washed three times with 0.02% Tween 20 in PBS and blocked with 1% BSA in PBS for 1 h at 25 °C. Samples were serially diluted in 0.25% BSA-PBS and incubated for 2 h at 25 °C. HRP-conjugated rabbit anti-mouse IgG antibody (1:2,000, Pierce) or anti-mouse subclass-specific antibodies (1:5,000, Southern Biotech) was added and followed by colorimetric assay using substrate tetramethylbenzidine and a Victor III microplate reader (PerkinElmer). Titters represent the highest dilution of samples showing a twofold OD_{450} value over controls. Neutralizing antibodies were measured by a standard virus neutralization assay. Sera were heat-inactivated, diluted first tenfold, then in twofold steps in MEM with 2% FBS. Fifty p.f.u. of HSV-2 was added per well and incubated at 37 °C for 1 h. Plaque assays were done. The titers were expressed as the reciprocal of the twofold serial dilution preventing the appearance of the cytopathic effects. Each assay was done in triplicate.

For measuring gD-specific, antibody-producing plasma cells, the 96-well ELISPOT plates (Millipore) were coated with 5 µg/ml gD and blocked with RPMI 5% FCS (Invitrogen) for 90 min at 37 °C and 5% CO2. Serial dilutions of bone marrow single-cell suspensions were prepared in RPMI and incubated in the coated wells for 24 h at 37 °C in 5% CO2. Cells were removed, and plates were washed 5 times with 0.1% Tween 20 in PBS, then incubated with biotin-labeled goat anti-mouse, IgG-specific antibody (1:1,500, Sigma) for 2 h. After washing the cells, with PBS, the avidin-conjugated HRP (1:2,000, Vector Laboratories) was added and incubated for 1 h, followed by substrate from the AEC kit (BD Biosciences). Spots were counted with ELISPOT Reader and analyzed with software (Zeiss). Mouse cytokines IFN-γ, IL-2 and IL-4 from the cell culture supernatant were analyzed by ELISA according to the manufacturer’s instructions (BD Biosciences).

**Immunofluorescence.** Immunofluorescence was performed as previously described36. Briefly, frozen serial sections of tissues were cold-fixed in acetone for 3 min at 4 °C and blocked with 10% normal goat serum and stained with biotin-PNA (tergalonal centers, red), Alexa 647-IgD or anti-B220 (B cells, green), followed by Alexa 555-avidin or 488 Fluor-conjugated IgG of the corresponding species. After each step, cells were washed at least three times with 0.1% Tween-20 in PBS. Cover slips were mounted on slides with Prolong TM mountant kit (Molecular Probes) and examined using a Zeiss LSM 510 confocal fluorescence microscopy. Images were processed by Adobe Photoshop 7.0.

**Passive transfer of immune sera.** Sera were collected from 3–5 mice per group 4 weeks after the immunization, then pooled, heated inactivated and stored frozen at −80 °C until use. Mice received a single intraperitoneal injection of 0.3 ml immune sera 3 d before challenge to allow distribution and equilibration of antibody to all tissues before virus inoculation. Mice were challenged intravaginally with 1 × 10^4 p.f.u. HSV-2 186 strain.

**Statistics analysis.** To compare survival curves, we used Kaplan-Meier log-rank analyses. Antibody titers, serum gD concentration, cytokine concentration and virus titers were assessed by using the unpaired two-tailed t-test. Graph Pad Prism 5 provided the software for the statistical analysis.
